

HST MID-UV IMAGING OF NEARBY GALAXIES

Rogier A. Windhorst, Violet A. Taylor, and Rolf A. Jansen

Department of Physics and Astronomy, Arizona State University, Box 871504, Tempe, AZ 85287

Abstract We summarize Hubble Space Telescope projects that imaged a significant sample of nearby galaxies of all types and inclinations in the mid-UV with WFPC2 and some in the near-IR with NICMOS. The sample emphasizes high-surface brightness late-type, irregular, peculiar and merging galaxies, since these objects are the most prevalent at high redshifts. The sample is used to establish a local benchmark for quantitative classifications of galaxies seen by *HST* in their rest-frame UV, and in the next decade also by the James Webb Space Telescope.

We review how nearby galaxies change their rest-frame structure and morphology from the rest-frame UV to the optical as a function of galaxy type and inclination, and other studies that are being done with this *HST* sample. When observed in the rest-frame mid-UV — early- to mid-type galaxies are more likely misclassified as later types than late-type galaxies are misclassified as earlier types. This is because later-type galaxies are dominated by the same young and hot stars in all filters from the mid-UV to the red, and so have a smaller “morphological K-correction” than true earlier type galaxies. This K_{morph} can explain a small part, but certainly not all of the excess faint blue late-type galaxies seen in deep *HST* fields. Contrary to early–mid-type galaxies, the majority of late-type galaxies become redder outward. While young UV/blue-bright stellar populations dominate their inner morphology, most late-type galaxies are inferred to have a significant halo or (thick) disk of older stars. We discuss these results in a cosmological context.

Keywords: galaxies: elliptical — spiral — irregular — mergers — peculiar — ultraviolet

1. The Need to Reliably Classify Faint Optical Samples

Since the mid 1990’s, faint galaxies have been observed systematically with the *Hubble Space Telescope* (*HST*). The best statistics, spatial sampling, and areal coverage are achieved in the red, and good *HST* structural information is available today for $\gtrsim 10^5$ galaxies with $I \lesssim 26\text{--}27$ mag. These galaxies come from the two Hubble Deep Fields (“HDF”s; Williams et al. 1996, 1998), the UltraDeep Field (UDF; Beckwith et al. 2004), their flanking fields, the *HST* Medium-Deep Survey, and other *HST* parallel surveys (e.g., Griffiths et al. 1994; Driver et al. 1995a; Abraham et al. 1996, 1999; Roche et al. 1997). The median half-light radius of faint field galaxies with $I \sim 26$ mag is $r_e \simeq 0.2\text{--}$

0.3'' (Odewahn et al. 1996, Cohen et al. 2003). *HST*'s 2.4 m aperture limits the useful wavelength for proper galaxy classification to $4000 \lesssim \lambda \lesssim 8000 \text{ \AA}$, because of the high spatial resolution and good sampling required. *HST* can determine morphology and structure with relative ease for a very large number of galaxies, and so explore a part of parameter space that constrains galaxy formation and evolution, which is complementary to spatially resolved spectroscopy and kinematics (see Koo 2004 and Le Fèvre 2004; this Vol.).

The most dramatic result from these *HST* studies was that at faint fluxes, late-type/irregular galaxies dominate the faint blue galaxy counts (Driver et al. 1995a; Glazebrook et al. 1995; Odewahn et al. 1996; Windhorst et al. 1997, 2000). These are believed to be star-forming galaxies that underwent substantial evolution since $z \lesssim 3-4$ (Ellis et al. 1996; Pascarelle et al. 1996; Abraham et al. 1999). Ellipticals and early-type spirals evolved much less since $z \lesssim 1$ (Driver et al. 1995a; Lilly et al. 1998; Cohen et al. 2003). Driver et al. (1998) suggested differential evolution of galaxies as a function of type, implying a gradual formation of the Hubble sequence with cosmic time.

2. The Morphological K-correction and How to Address it

In the deepest *HST* fields, where reliable classifications are achievable to $I \lesssim 26 \text{ mag}$ (e.g., Odewahn et al. 1996; Driver et al. 1998), the sampled redshift range is $z \simeq 1-3$, while the bulk of the galaxies is at $z \lesssim 2$. Faint high redshift galaxies observed in the *I*-band are therefore primarily seen in the rest-frame mid-ultraviolet (mid-UV), or $2000-3200 \text{ \AA}$, which primarily traces high surface brightness ("SB") regions populated by high densities of young ($\lesssim 1 \text{ Gyr}$) hot stellar populations. The reliability of results derived from faint *HST* galaxy morphology is therefore fundamentally limited by the uncertain rest-frame mid-UV morphology of nearby galaxies. Although these faint, late-type/irregular objects resemble some classes of nearby late-type and peculiar galaxies (e.g., Hibbard & Vacca 1997), they need not be physically late-type objects. Instead, they may be earlier-type galaxies that look dramatically different in the rest-frame UV. Because of the wavelength dependence of nearby galaxy morphology (especially towards the UV), faint galaxy classifications will depend on the rest-frame wavelength sampled. This "morphological K-correction" can be quite significant, and must be quantified in order to distinguish genuine evolutionary effects from simple band-pass shifting.

Morphological K-corrections were derived from *UIT* images by Bohlin et al. (1991) and Giavalisco et al. (1996), showing that nearby galaxy morphology can change quite dramatically below $3600-4000 \text{ \AA}$, where the hot (young) stellar population — located mainly in spiral arms and H II-regions — dominates the spectral energy distribution (SED) and where bulges essentially disappear (Burgarella et al. 2001; Marcum et al. 2001; Kuchinski et al. 2001). Galaxies

therefore often appear to be of later Hubble type the further one looks into the rest-frame UV. Qualitatively, this is easy to understand: in the optical/near-IR, we see the accumulated luminous phases of long-lived (>1 Gyr) stars, which emit most of their energy at longer wavelengths, whereas the mid-UV samples the star-formation rate (SFR) averaged over the past Gyr or less. The mid-UV includes the longest wavelengths where young stars can dominate the integrated galaxy light, and traces primarily presently active star forming regions, or those regions where star-formation (SF) has only recently shut down. A number of authors have explored the effects of band-pass shifting using multicolor optical images to extrapolate to the rest-frame UV on a pixel-by-pixel basis using both ground-based data (e.g., Hibbard & Vacca, 1997; Brinchmann et al. 1998), mid-UV FOCA balloon images (Burgarella et al. 2001), *UIT* far-UV images (Kuchinski et al. 2000), and *HST* images of galaxies at moderate redshifts (Abraham et al. 1999; Bouwens, Broadhurst, & Silk 1998). The galaxy shape and size distributions measured in deep *HST* images appear to considerably exceed the effects of band-pass shifting alone.

To address these issues unambiguously, we present a systematic *HST* imaging project with the Wide Field and Planetary Camera 2 (“WFPC2”) in the mid-UV and red for a representative sample of ~ 100 nearby galaxies. A subset was also imaged with the Near-Infrared Camera and Multi-Object Spectrograph (“NICMOS”) in H-band to study the older stellar populations, and with the Advanced Camera for Surveys (“ACS”) in $H-\alpha$ to trace their recent SF and correlate this with the mid-UV images. This survey will help us better understand the *physical* drivers of the rest-frame mid-UV emission, i.e., the relation between SF and the global physical characteristics of galaxies, their recent SF history, and the role of dust absorption/scattering. Details are given in Windhorst et al. (2002), Odewahn et al. (2002; & this Vol.), Eskridge et al. (2003), de Grijs et al. (2003), Jansen (2004; this Vol.), and Taylor et al. (2004).

3. Strategy, Sample Selection, and HST Observations

With the *HST* WFPC2, we imaged ~ 100 nearby galaxies through one or, whenever possible, two wide-band mid-UV filters below the atmospheric cutoff: F300W ($\lambda_{cent} \simeq 2930 \text{ \AA}$; $\Delta\lambda \simeq 740 \text{ \AA}$ FWHM) and F255W ($\lambda_{cent} \simeq 2550 \text{ \AA}$; $\Delta\lambda \simeq 395 \text{ \AA}$ FWHM). To this we add short red F814W exposures to provide red-leak removal and study the older stellar population. The F255W, F300W filters are logarithmically about equally spaced in λ from Johnson U , B , and so add significantly to the ground-based optical–near-IR color baseline.

Over the last decade, several groups did systematic ground-based imaging of a large number of nearby galaxies covering all Hubble types and inclinations. Most of these were observed in $UBVR$, but a subset also in the near-IR IJK filters (Eskridge et al. 2002, see also this volume). We selected our HST sam-

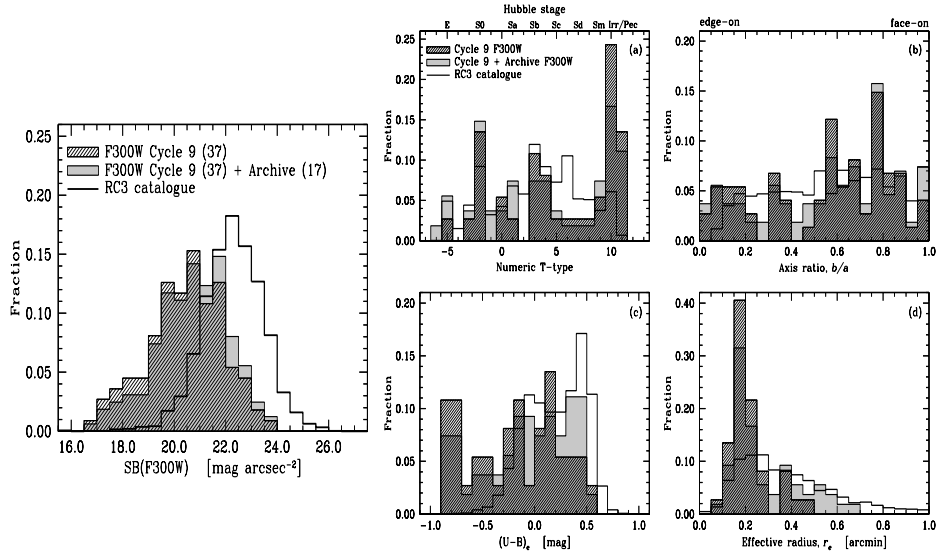

Fig. 1 (LEFT PANEL): The distribution of predicted average mid-UV surface brightness (SB) out to r_e for the galaxies observed in *HST* Cycle 9 (hashed histogram) and for the full galaxy sample (solid histogram), which includes galaxies with mid-UV images in the *HST* Archive. For comparison, we show the SB-distribution for the 3009 galaxies in the RC3 with measured B_T , $(U-B)$ and r_e (open histogram). **Fig. 2a–2d (RIGHT FOUR PANELS):** Other properties of the selected *HST* mid-UV galaxy sample. As in Fig. 1, we plot the Cycle 9 galaxies (hashed), the full sample (solid), and the RC3 (open) versus (a) morphological type; (b) apparent axis ratio, b/a ; (c) average $(U-B)$ color out to r_e ; and (d) effective radius r_e . Our sample approximates the RC3 distribution, except that for comparison with high redshift samples we emphasize the later types, bluest galaxy colors, and smallest sizes.

ple of ~ 100 galaxies from these ground-based samples, which include: (1) 86 face-on spirals (de Jong & van der Kruit 1994); (2) 220 spirals from the OSU survey (Eskridge et al. 2000, 2002); (3) 113 galaxies from Frei et al. (1996); (4) 100 galaxies with 1500 Å and 40 with 2500 Å images from the *Astro/UIT* mission (Kuchinski et al. 2001; Marcum et al. 2001); (5) 48 edge-on galaxies (de Grijs et al. 1997); (6) 150 UGC galaxies that are morphologically irregular, peculiar, or mergers (Hibbard & Vacca 1997); and (7) 49 late-type dwarf spiral galaxies and compact, high-SB luminous blue galaxies (Matthews & Gallagher 1997). The last two samples provide likely local counterparts of the peculiar and irregular galaxies seen with *HST* in large numbers at high redshifts.

The selection criteria for inclusion in the *HST* sample are: (a) B -band half-light radius $0.1' \lesssim r_e \lesssim 1.0'$, so that the object fits inside a WFPC2 or NIC3 mosaic; (b) predicted average mid-UV SB out to $r \simeq r_e$: $18 \lesssim \mu_{F300W} \lesssim 22.5-23.0$ mag arcsec⁻² (Fig. 1), so that a galaxy can be detected out to $r \simeq 2-3r_e$ in one orbit with sufficiently high S/N to allow structural features to be recognized; (c) distribution of Hubble types and (d) the distribution over apparent axis ratio (inclination) should both be representative for nearby galaxy samples (Fig. 2).

Fig. 1 shows that the galaxies observed with *HST* have higher predicted mid-UV SB than the median in the RC3, which is $\mu_{F300W} \simeq 22.3 \text{ mag arcsec}^{-2}$. This is not an overriding concern, since high-redshift samples are similarly biased (or more so) in favor of high-SB galaxies due to the severe $(1+z)^4$ cosmological SB-dimming. Based on Fig. 1, one could apply weights to each observed *HST* galaxy to better represent the true local galaxy distribution when complete samples are in order. Figures 2a–2d show the distributions of the *HST* mid-UV sample over morphological type, axis ratio b/a , (U–B) color within r_e , and effective radius r_e . Our selected mid-UV sample deliberately overemphasizes late-types, bluer, and smaller galaxies, since these are the dominant galaxy population at high redshifts. Fig. 2b shows that our selected mid-UV galaxies have a similar b/a distribution as the RC3. Since there is no significant trend in the galaxy b/a distribution from the RC3 level ($B \lesssim 15 \text{ mag}$) to the HDF limit ($B \lesssim 28 \text{ mag}$; Odewahn et al. 1997), our nearby *HST* comparison sample is thus a fair one in terms of galaxy ellipticities at all redshifts.

In total, ~ 100 galaxies were observed with WFPC2 in Cycle 9–10, and about 12 with NICMOS/NIC3 in H-band and 20 with ACS in $H\text{-}\alpha$ in Cycle 12 (Jansen 2004; this Vol.). Typically, we exposed $2 \times 800\text{--}1000 \text{ sec}$ in F300W and $2 \times 100\text{--}160 \text{ sec}$ in F814W, while some exposures came from the HST Archive. Exposures times were made flexible to optimally use the full *HST* orbit allocated per galaxy. The resulting 1-orbit SB-sensitivity matches that achieved in deep *HST* I-band images for faint galaxies, accounting for SB-dimming. The resulting point source sensitivity resolves many galaxies into their brightest star-forming regions (OB associations, young star clusters), and resolves the brightest stars in the nearest objects.

4. Discussion of the HST Images

In this section, we give a high level discussion of the *HST*/WFPC2 (Fig. 3) and some of the recent NIC3 images obtained thus far (Fig. 4). The *HST* images have in general a much higher dynamic range than the ground-based images. This sometimes leads to a different galaxy classification than in the ground-based images or the RC3, and also makes it difficult to properly display the full range of structures seen within a galaxy. The best display of the *HST* images is given in the electronic version of Windhorst et al. (2002).

- **Early-type Galaxies:** The regular early-type galaxies (elliptical and S0's) in our sample show in general a significant increase in SB from the mid-UV to the red, reflecting an overall lack of a young stellar population, as also seen in the far-UV *UIT* images of Marcum et al. (2001) and Kuchinski et al. (2000). Out of 7 early-type galaxies imaged, two have small blue nuclear features. Two galaxies are merger remnants and have significant dusty disks in the mid-UV, but will likely soon evolve into early-type galaxies. Three early-type galaxies

Fig. 3: Summary of our *HST*/WFPC2-images ($75'' \times 75''$ FOV) of nearby galaxies in F300W (“mid-UV”; left panels) and F814W (right panels). **(Row 3.1)** The Seyfert UGC08823 with an old stellar population in F814W, and the merger remnant UGC05101 which is dusty in the mid-UV; **(Row 3.2)** The early-type spiral NGC2551 and mid-type grand-design spiral NGC6753; **(Row 3.3)** The late-type barred spiral NGC5257 and the small spiral ESO418-008; **(Row 3.4)** The late-types ESO487-019 and UGC10445, each with significant K_{morph} (which is an exception rather than the rule for the late-type galaxies observed in our sample); **(Row 3.5)** The mergers UGC06471-2 and UGC08677-8 with various wavelength dependent structures. The best full-size displays are given in the electronic version of Windhorst et al. (2002).

become dominated by point sources in the mid-UV, indicating weak optical-UV AGN, Seyfert, or LINER nuclei (Fig. 3.1). While these are small number statistics, their presence in our sample is due to our pre-selection of galaxies with high predicted average SB in the mid-UV within r_e , resulting in a number of early-type galaxies that are dominated in the mid-UV by AGN.

If AGN generally reside in bulge-dominated galaxies (e.g., Magorrian et al. 1998), then the red and old stellar population of the underlying early-type galaxies will be generally faint in the UV, but the presence of a (weak) AGN will result in blue (U-B) colors and therefore a high SB the mid–near UV, and so inclusion into UV-selected samples. Similarly, ground-based U- or B-band selected surveys result in significant numbers of point-like AGN in early-type galaxies at moderate redshifts ($z \gtrsim 0.3$), which are thus classified as QSO’s. However, had these objects been selected from the ground at much longer wavelengths (i.e., in the *I*-band), then they would have shown up as early-type galaxies in good seeing. This leads us to wonder to what extent the (strong) cosmological evolution of AGN selected through their UV/blue excess at modest redshifts (Koo & Kron 1988; Boyle et al. 2000) could in part be due to a “morphological K-correction” of early-type galaxies with weak AGN — the strong SB-dimming of their UV-faint stellar population will render the early-type AGN host galaxies invisible at intermediate to higher redshifts.

• **Mid-type Spirals:** In general, spiral arms are more pronounced in the mid-UV, as *UIT* showed to be generally true in the far-UV (Bohlin et al. 1991, Hill et al. 1992, Kuchinski et al. 2001, Marcum et al. 2001). However, mid-type spirals and star-forming galaxies appear in general more similar from the mid-UV to the optical than early-type galaxies (Fig. 3.2 & 3.3). Some appear as later types in the mid-UV, and a few show drastic changes in type from the optical to the mid-UV, equivalent to a change in T-type of $\Delta T \gtrsim 3$ (Fig. 3.4b). One galaxy shows a spectacular resonance ring of hot stars, while the remainder disk becomes essentially invisible in the mid-UV (Eskridge et al. 2003).

We observe a variation in color of the galaxy bulges/centers in spirals, and a considerable range in scale and SB of the individual star-forming regions. Dust features in mid-type spirals can be well traced by comparing the F300W to the F814W images, and are visible in lanes or patches (possibly trailing spiral density wave patterns?), in pockets, and/or bubbles. A curious feature is that almost without exception, the mid-type spirals in our sample have their small nuclear bulges bisected by a dust-lane, which is often connected to the inner spiral arm structure, as seen by comparing the F814W and mid-UV images. This is interesting in the context of the finding that all bulge-dominated systems have a central black-hole with an average mass $M_{bh} \simeq 0.005 \times M_{bulge}$ (Magorrian et al. 1998). The small nuclear dust-lane in most mid–late-type spirals may be involved in feeding the inner accretion disk, if present. Some edge-on galaxies are very faint in F300W when compared to F814W, others

emit/transmit significantly more in F300W, with some intermediate cases. All show a F300W/F814W flux ratio increasing from the inside out, as expected for a decreasing dust content from the inside out, and/or a strong radial gradient in the stellar population, if we assume that the dust and stars are well mixed (i.e., the stars are not preferentially located in front of most of the dust; see e.g., Jansen et al. 1994, 2000; Witt & Gordon 1996; Kuchinski et al. 1998).

- **Late-type Galaxies and Irregulars:** The late-type and irregular galaxies imaged are a heterogeneous mixture. The majority of these galaxies show a F300W morphology that is similar to F814W. Important differences are seen, however, due to recognizable dust-lanes blocking out the F300W light. Dust is visible in pockets, holes or bubbles, perhaps due to supernova-induced outflows, or outflows fueled by bright star-forming regions, such as seen in M82 at *HST* resolution (de Grijs et al. 2001). Some late-type galaxies are physically smaller galaxies with what appears to be the beginning of spiral structure. Others are Magellanic Irregulars with various regions of stochastic SF. Star-formation “ridges” are seen in late-type galaxies, as well as hot stars or star-clusters that are particularly conspicuous in the mid-UV (F300W and/or F255W). A few late-type galaxies would be classified significantly differently when observed in the mid-UV than in the F814W passband, especially when observed under less than perfect atmospheric seeing conditions (see Fig. 3.4). A quantitative discussion of the classification changes as a function of rest-frame wavelength will be given by Taylor et al. (2004).

- **Peculiars and Mergers:** The majority of the peculiars and interacting galaxies show a F300W morphology that is similar to that in F814W. Several mergers have spectacular dust-lanes that thread along with the spiral arms, which are tidally distorted during the interaction (Fig. 3.5), while most others have absorption in apparently random locations associated with a star-burst.

5. Galaxy Outskirts from a Cosmological Perspective

The combined *HST*+ground-based UBV_R light profiles show that early–mid type galaxies have only small radial color-gradients in the outer parts, where disks tend to get somewhat bluer at larger radii (Fig. 4 here; de Jong & van der Kruit 1994; de Jong 1996; de Grijs et al. 1997; Jansen et al. 2000). Corrected for reddening by dust, this behavior indicates a (thin) disk that grows with cosmic time through the infall of gas and minor mergers that did not recently upset the disk. Remarkably, the majority of the *late-type* galaxies in our sample shows the opposite behavior, becoming significantly *redder* at larger radii. Fig. 4a and 4b compare an example of each trend, and in Taylor et al. (2004) we quantify the color-gradients for the total sample. In general, color-gradients

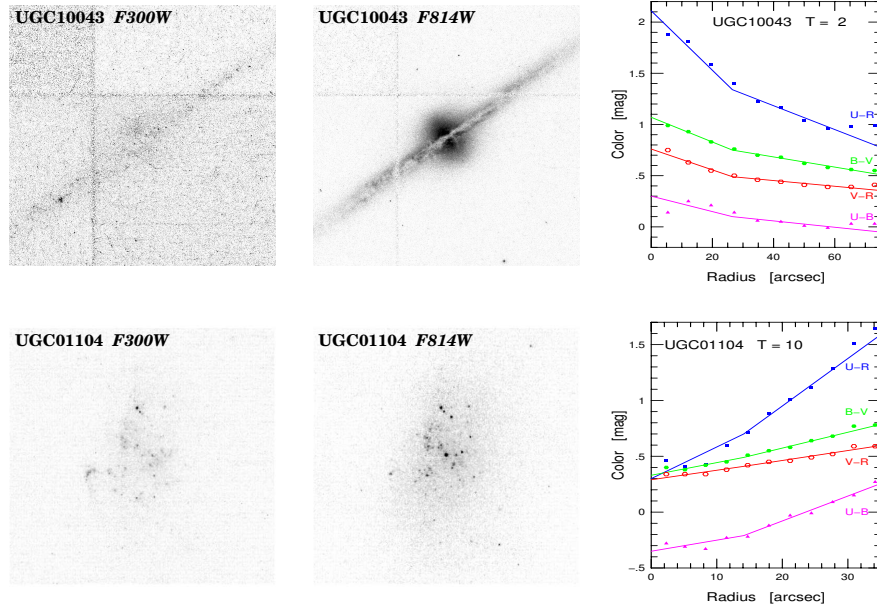

Fig. 4: WFPC2-images in F300W and F814W and color-gradients in (U-B), (B-V), (V-R), and (U-R) for (a) UGC10043 [top] and (b) UGC01104 [bottom]. UGC10043 shows the usual behavior for early-mid-type spirals of getting *bluer* with increasing radius. Irregular galaxy UGC01104, on the other hand, becomes progressively *redder* toward its outer regions. This is the more common behavior for late-type/irregular galaxies in our HST samples, and suggest the existence of an old halo or (thick) disk.

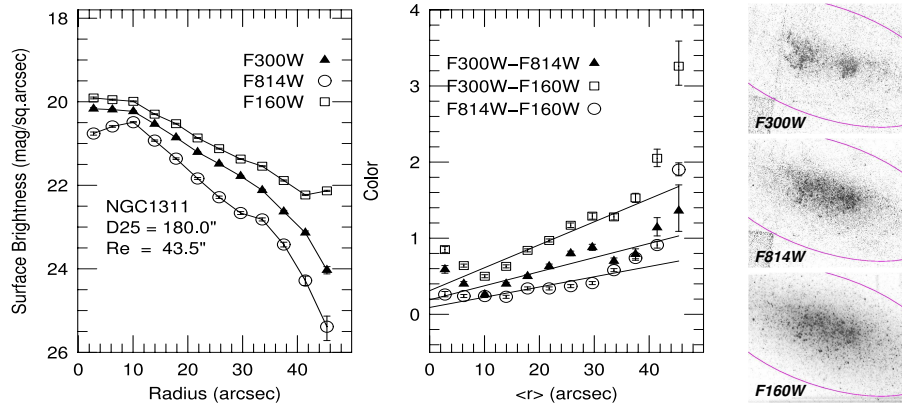

Fig. 5: Profiles of surface brightness [left] and color [middle] measured from our HST/WFPC2 F300W, F814W and NIC3 F160W images [right]. The ellipses in each image correspond to the outermost points used in the profiles. NGC1311 is an Sm galaxy that is well-resolved with HST into its stellar populations from the mid-UV to the near-IR and that *becomes redder* with increasing distance from its center, a trend seen in the majority of late-type galaxies in our sample. Significantly more stars are seen in H-band (through most of the dust), and a dimmer unresolved, older stellar population is apparent.

get redder outwards for the majority of late-type galaxies, and this is in general more often seen for galaxies of lower luminosity, smaller half-light radius, and lower average SB (Tully et al. 1996; Jansen et al. 2000; Taylor et al. 2004). This trend appears in all filters, thereby ruling out sky-subtraction errors as the major cause (Fig. 5), and appears somewhat more pronounced for rounder galaxies than for flatter galaxies. *While young UV/blue-bright stellar populations clearly dominate their inner morphology, most late-type galaxies thus appear to have a significant old halo or (thick) disk population.*

The idea of old Population II envelopes in dwarf irregular galaxies was first proposed by Baade (1958). Tully et al. (1996) found a significant number of nearby dwarf galaxies with red outer envelopes, and Jansen et al. (2000) found a similar result in the NFGS Survey. Recently, Dalcanton & Bernstein (2002) suggested red envelopes in a sample of late-type edge-on galaxies. These findings constrain hierarchical models of galaxy formation (e.g. Katz et al. 1999; Kauffmann et al. 1999). Dalcanton & Bernstein (2002) favor a scenario where late-type galaxies formed in an early epoch of significant mergers ($\gtrsim 6$ Gyr ago or $z \gtrsim 1$), resulting in *red* outer colors, which they explain as an old (thick) disk. These late-type galaxies would have remained largely undisturbed since $z \simeq 1$, and recently undergone only more centrally concentrated SF.

Important related clues to the nature of late-types can be found from the galaxy counts as a function of type, which are now available over the entire flux range $15 \lesssim B \lesssim 27$ mag (Cohen et al. 2003), so they can be properly normalized at the bright end. At the faint end ($B \gtrsim 24$ mag or $z \gtrsim 1$), the type-dependent counts not only show the well-known excess of late-type galaxies, but also show a significant excess of early–mid types at $z \gtrsim 1$. Cohen et al. (2003) explain this as the Cosmological Constant itself gradually turning off the epoch-dependent merger rate, when it started to significantly affect the expansion at $z \lesssim 1$. Today’s red outskirts in late-type galaxies could thus be the smoking gun of the cosmic acceleration induced by Λ . As a consequence, most (major) mergers occurred early-on in galaxies of all types and luminosities, so halos and (thick) disks were formed early-on and are still seen as such today. Disks of giant galaxies are still growing today, because of infalling surrounding gas and minor mergers, but are otherwise evolving passively. Late-type low-luminosity systems are mostly left with stochastic star-formation in their inner parts today, which is no longer fed by their environment in a major way.

6. Discussion and Conclusions

In summary, our *HST* mid-UV imaging data base shows that in galaxies where star-formation is sufficiently pronounced, it can dominate the morphology from the mid-UV through the optical, resulting in very little change in morphology from the UV to the red. However, when stellar populations older than about 1

Gyr produce most of the optical light, we see changes in morphology between the optical — where these stars tend to produce relatively regular structures due to the effects of orbital mixing within the galaxies — and the mid-UV — where younger stars whose locations still reflect the distribution of their birthplaces. An additional complication is introduced by the presence of dust obscuration. Dust lanes or dust clouds that are nearly transparent in the visible can be opaque in the mid-UV, thereby changing the apparent morphology. In summary, the qualitative results from our study are:

- (1) High-SB early-type galaxies in the optical show a variety of morphologies in the mid-UV that *can* lead to a different morphological classification, although not necessarily always as later-type. The often rather peculiar mid-UV morphology of early-type galaxies is generally quite different than that of the real late-type galaxies as seen in the mid-UV.
- (2) About half of the mid-type spirals in the optical appear as later morphological types in the mid-UV, but not all mid-type spiral galaxies do look dramatically different in the mid-UV. Their mid-UV images show a considerable range in the scale and SB of individual star-forming regions. A comparison of F300W to F814W images yields good sensitivity to dust features.
- (3) The majority of the heterogeneous subset of late-type, irregular, peculiar and merging galaxies display mid-UV morphologies that are similar to those seen in the red, but with important differences due to recognizable dust-features absorbing the bluer light, and due to hot stars, star-clusters, and star-formation “ridges” that are bright in the mid-UV. Less than one third of the galaxies classified as late-type in the optical appears sufficiently different in the mid-UV to result in a different classification.

Our *HST* mid-UV survey of nearby galaxies shows that — when observed in the rest-frame mid-UV — early- to mid-type galaxies are more likely misclassified as later types than late-type galaxies are misclassified as earlier types. This is because later types are dominated by the same young and hot stars in all filters from the mid-UV to the red, and so have a smaller “morphological K-correction” than true earlier types. The morphological K-correction can thus explain part, but certainly not all of the excess faint blue late-type galaxies seen in deep *HST* fields. Classification of faint galaxies in the rest-frame mid-UV will likely result in some fraction of early–mid type galaxies being misclassified as later-types, likely a larger fraction than vice versa.

In conclusion, it is unlikely that the morphological K-correction can explain all of the faint blue galaxy excess as misclassified earlier-type galaxies. And the morphological K-correction cannot explain the slight excess of *early–mid type* galaxies at faint magnitudes ($B \gtrsim 24$ mag) with respect to passively evolving models, as found by Odewahn et al. (1996) and Cohen et al. (2003), since the main misclassification error goes in the opposite direction, as discussed above. Instead, our mid-UV survey seems to support the conclusion

of Cohen et al. (2003) that the number of faint galaxies is larger than the non-evolving predictions *for all galaxy types*, but more significantly so for the later types. They give a possible explanation of this finding in terms of hierarchical formation models, where the Cosmological Constant itself was responsible for gradually turning off the strongly epoch-dependent merger rate at $z \lesssim 1$, since in WMAP cosmology the universe became dominated by Λ and started expanding exponentially for $z \lesssim 0.4$. Hence, Λ may be responsible for the gradual transition from the $z \gtrsim 1$ Universe, where galaxy formation and evolution was driven by major mergers, to the Universe at $z \lesssim 0.4$, where at best minor mergers or infall affected the more passive, secular evolution of giant galaxies.
